We have investigated the proximity effect in superconductor/ferromagnet junctions in a systematic manner to discuss the relation between the zero energy peak (ZEP) of the local density of states (LDOS) and spin-triplet odd-frequency paring. By exactly solving the nonlinear Usadel equations, we have found that the ZEP is realized in a wide range of geometrical and material parameters in the case of the noncollinear magnetization. This strongly suggests the robustness of the ZEP induced by spin-triplet odd-frequency paring in such systems. We also found that the crossover from singlet to triplet paring can be detected by measuring the F layer thickness dependence of the ZEP height. Further, we show how to observe signatures of spin-triplet odd-frequency paring and the paring crossover by the LDOS measurements. Our results provide a direct way to experimentally detect signatures of odd-frequency paring state.

I. INTRODUCTION

The study of proximity effect in superconductor (S) - ferromagnet (F) hybrid structures has its long history following the first theoretical proposal of the so-called π state in a mesoscopic ring containing SFS Josephson junction.[1]. The penetration depth of Cooper pairs into a diffusive normal metal (N) is characterized by the length scale $\xi_T = \sqrt{\hbar D/2\pi T}$, whereas in a ferromagnet this length scale is considerably shorter and is given by $\xi_h = \sqrt{\hbar D/2E_{\rm ex}}$. Here T is temperature, D is the diffusion constant, and $E_{\rm ex}$ is the magnitude of the exchange potential in the ferromagnet. Since the exchange field affects differently electrons with opposite spins, spin-singlet Cooper pairs are fragile under the exchange potential. In addition to a short penetration length, the pairing function of spin-singlet pair spatially oscillates with changing its sign under the exchange potential,[2,3] which enables the π states in SFS junctions.[4] Although the π state was predicted theoretically in 1970's, it has been confirmed experimentally only recently.[5–7] The details of research progress have been summarized in several review papers.[8–10]

Bergeret, Volkov and Efetov[11] proposed theoretically new type of proximity-induced superconducting state in ferromagnets, the so called long-range spin-triplet pairing state. Inhomogeneous magnetic structures near the SF interface (see Fig. 1) rotate the spin direction of an electron, which induces equal spin-triplet s-wave Cooper pairs in ferromagnets.[10,12–14] Such Cooper pairs should have the odd-frequency symmetry to satisfy the requirement from the Fermi-Dirac statistics of electrons. Since equal spin-triplet pairs are not suppressed by the exchange potential, they have the long range penetration length into ferromagnets characterized by ξ_T. Experimentally such effect has been observed first as the long-range Josephson coupling in SFS junctions,[15] where the ferromagnet is a half-metallic CrO_2 compound. In clean half-metallic SFS junctions the equal-spin triplet pairs can have the odd-parity even-frequency symmetry,[16] whereas in the experimentally relevant dirty limit case the equal-spin triplet even-parity s-wave odd-frequency symmetry is the only possible choice. The experiment[15] as well as anomalous conductance oscillations observed in SF hybrids[27] stimulated much theoretical[17,19,20] and experimental work[21–26]. As a result, a number of signatures of triplet correlations have been observed. However, no experiment so far has reported direct and unequivocal evidences of long-range spin-triplet odd-frequency pairs.

Existing theories[11,17–20] predict that the presence of odd-frequency pairs causes the enhancement of the zero-energy local density of states (LDOS).[11,17–20] According

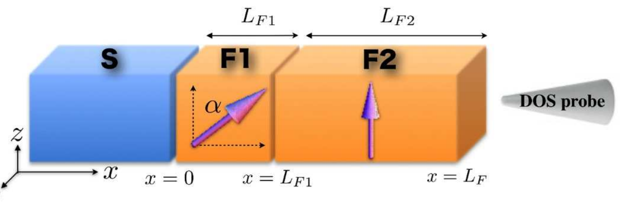

FIG. 1: (Color online) Model of an SF junction for observation of spin-triplet paring through the local density of states (LDOS) measurement. The magnetization directions in F1 and F2 layers are collinear ($\alpha = 0$) or noncollinear ($\alpha = \pi/2$).

to a number of theoretical papers on the proximity effect in various SF hybrid structures,[28–53] the relative fraction of odd-frequency pairs to even-frequency pairs depends sensitively on junction parameters such as the resistivity of F, the transparency of SF interface, the amplitude of the exchange energy E_{ex}, and the geometry of junctions. To observe clear evidence of spin-triplet odd-frequency pairs in experiments, theoretical studies should show a way how to optimize the fraction of odd-frequency spin-triplet pairs in wide parameter range tunable in actual experiments.

In this paper, by solving full-spin Usadel equation[54,55] in a wide parameter range, we systematically calculate the LDOS at a surface of a diffusive ferromagnet connected with a metallic superconductor. In particular, we focus on a relation between the magnitude of the zero-energy peak (ZEP) in the LDOS and the fraction of triplet odd-frequency pairs and show the robustness of the presence of the ZEP. It should be noted that ZEP formation has been reported in measured tunneling conductance spectra in oxide-based SF hetero-structures with nonuniform ferromagnets.[56–60] However the physical origin of ZEP in these structures is still unclear. Therefore we propose an experimental method to explicitly detect a signature of spin-triplet paring by measuring ZEP.

This paper is organized as follows. In Sec. II, we present a model of an SF junction and describe the numerical method to solve the nonlinear Usadel equation in such system. The numerical results of the LDOS for various parameters and discussion of the robustness of ZEP are presented in Sec. III. In Sec. IV, the summary of our results is presented. Throughout the paper we confine ourselves to the regime of zero temperature and put $k_B = 1$.

II. NONLINEAR USADEL EQUATION

In this section, we will introduce a model of an SF junction and describe how to numerically solve the nonlinear Usadel equation with inhomogeneous magnetization in a ferromagnet F. The system we consider is an one-dimensional diffusive SF junction where magnetization in the F layer is either homogeneous or rotating like illustrated in Fig. 1. The rotation is introduced by dividing the F layer with thickness L_F into F1 and F2 layers where magnetization are in general non-collinear. The thicknesses of F1 and F2 layers, the SF barrier resistance, and the F layer resistance are respectively defined by L_{F1}, L_{F2}, R_B, and R_N. The exchange field in the F2 layer is aligned along the z axis, while that in the F1 layer is misaligned by angle α in the x-z plane. Importantly, the misorientation angle α in exchange-spring ferromagnets[61–63] can be experimentally controlled by applying an in-plane magnetic field. In our calculation we have assumed that the exchange energy E_{ex} in the F1 and F2 layers are the same, and the F1 and F2 interface is transparent.

Because of the spin-rotation of electrons in ferromagnets, we have to solve 4×4 matrix Usadel equation[54] given by,

$$i\hbar D \frac{d}{dx}\left(\check{g}\frac{d}{dx}\check{g}\right) - \left[\check{H}, \check{g}\right] = 0, \tag{1}$$

where D is the diffusion constant in F. Here Hamiltonian $\check{H}$ and the Green function $\check{g}$ are respectively defined by

$$\check{H} = \begin{bmatrix} \hat{E}(x,E) & \hat{\Delta}(x,E) \\ \underset{\sim}{\hat{\Delta}}(x,E) & \underset{\sim}{\hat{E}}(x,E) \end{bmatrix}, \tag{2}$$

$$\check{g}(x,E) = \begin{bmatrix} \hat{g}(x,E) & \hat{f}(x,E) \\ \underset{\sim}{\hat{f}}(x,E) & \underset{\sim}{\hat{g}}(x,E) \end{bmatrix}, \tag{3}$$

where

$$\hat{E}(x,E) = E\hat{1} - \boldsymbol{V}(x)\cdot\hat{\boldsymbol{\sigma}}, \tag{4}$$

$$\underset{\sim}{\hat{E}}(x,E) = \left\{\hat{E}(x,-E)\right\}^*, \tag{5}$$

$$\underset{\sim}{\hat{\Delta}}(x,E) = \left\{\hat{\Delta}(x,-E)\right\}^*. \tag{6}$$

Here $\hat{\sigma}_j$ with $j = 1,2,3$ are Pauli matrices and $\hat{\sigma}_0 = \hat{1}$ is the 2×2 unit matrix. The magnetic moment $\boldsymbol{V}(x)$ in a ferromagnet is defined as

$$\boldsymbol{V}(x) = \begin{cases} E_{\text{ex}}(\sin\alpha, 0, \cos\alpha) & \text{for} \quad 0 \le x \le L_{F1} \\ E_{\text{ex}}(0,0,1) & \text{for} \quad L_{F1} < x \le L_F \end{cases}. \tag{7}$$

Throughout this paper, $\check{\cdot}$ and $\hat{\cdot}$ indicate 4×4 and 2×2 matrices, respectively. In what follows, we only consider the s-wave spin-singlet pair potential in a superconductor, (i.e., $\hat{\Delta} = \Delta_0 i\hat{\sigma}_2$). The particle-hole symmetry results in

$$\underset{\sim}{\hat{g}}(x,E) = -\left\{\hat{g}(x,-E)\right\}^*, \tag{8}$$

$$\underset{\sim}{\hat{f}}(x,E) = -\left\{\hat{f}(x,-E)\right\}^*. \tag{9}$$

To solve Eq. (1), we use the Riccati parameterization[64–67] for the Green function, *i. e.*,

$$\check{g}(x,E) = \begin{bmatrix} \hat{g} & \hat{f} \\ \underset{\sim}{\hat{f}} & \underset{\sim}{\hat{g}} \end{bmatrix} = \begin{bmatrix} \hat{N} & \hat{0} \\ \hat{0} & \underset{\sim}{\hat{N}} \end{bmatrix} \begin{bmatrix} \hat{1} - \hat{\gamma}\underset{\sim}{\hat{\gamma}} & 2\hat{\gamma} \\ 2\underset{\sim}{\hat{\gamma}} & -(\hat{1} - \underset{\sim}{\hat{\gamma}}\hat{\gamma}) \end{bmatrix}, \tag{10}$$

where

$$\hat{N} = (\hat{1} + \hat{\gamma}\underset{\sim}{\hat{\gamma}})^{-1}, \tag{11}$$

$$\underset{\sim}{\hat{N}} = (\hat{1} + \underset{\sim}{\hat{\gamma}}\hat{\gamma})^{-1}. \tag{12}$$

Here Riccati parameters $\gamma(x,E)$ and $\underset{\sim}{\gamma}(x,E)$ are independent from each other. The normalization condition of the Green function is automatically satisfied under the parameterization, *i. e.*, $\check{g}\check{g} = \check{1}$. The derivative of the inverse matrix $\partial_x \hat{N}$ can be done as follows

$$\partial_x \hat{N} = - \hat{N}\hat{A}\hat{N}, \tag{13}$$

where

$$\hat{A} =(\partial_x \hat{\gamma})\underset{\sim}{\hat{\gamma}} + \hat{\gamma}\partial_x \underset{\sim}{\hat{\gamma}}, \tag{14}$$

which is obtained from an identity $\partial_x(\hat{N}\hat{N}^{-1}) = \hat{0}$.

Finally, the Usadel equation (1) is reduced to two partial differential equations for $\hat{\gamma}$ and $\underset{\sim}{\hat{\gamma}}$,

$$i\hbar D \left[\partial_x^2 \hat{\gamma} - \left(\partial_x \hat{\gamma}\right) \underset{\sim}{\hat{f}} \left(\partial_x \hat{\gamma}\right) \right] - \hat{E}\hat{\gamma} + \hat{\gamma}\underset{\sim}{\hat{E}} + \hat{\Delta} - \hat{\gamma}\underset{\sim}{\hat{\Delta}}\hat{\gamma} = 0, \tag{15}$$

$$- i\hbar D \left[\partial_x^2 \underset{\sim}{\hat{\gamma}} - \left(\partial_x \underset{\sim}{\hat{\gamma}}\right) \hat{f} \left(\partial_x \underset{\sim}{\hat{\gamma}}\right) \right] - \underset{\sim}{\hat{E}}\underset{\sim}{\hat{\gamma}} + \underset{\sim}{\hat{\gamma}}\hat{E} - \underset{\sim}{\hat{\Delta}} - \underset{\sim}{\hat{\gamma}}\hat{\Delta}\underset{\sim}{\hat{\gamma}} = 0. \tag{16}$$

After taking the complex conjugation and $E \to -E$ in the above equations, we find that $-\hat{\gamma}^*(x, -E)$ and $\underset{\sim}{\hat{\gamma}}(x, E)$ obeys the same equation. Thus we conclude that

$$\underset{\sim}{\hat{\gamma}}(x, E) = -\hat{\gamma}^*(x, -E). \tag{17}$$

At the interface between a ferromagnet and a superconductor, the Kupriyanov-Lukichev boundary condition[68] connects Green functions on both sides,

$$2\Gamma_B \check{g}\partial_x \check{g} = \left[\check{G}_S, \check{g}\right], \tag{18}$$

where

$$\check{G}_S = \left[\begin{array}{cc} g_s \hat{1} & f_s \hat{\sigma}_2 \\ f_s \hat{\sigma}_2 & -g_s \hat{1} \end{array} \right], \tag{19}$$

$$g_s =\frac{E}{\sqrt{E^2 - \Delta^2}}, \tag{20}$$

$$f_s =\frac{i\Delta}{\sqrt{E^2 - \Delta^2}}. \tag{21}$$

Here $\Gamma_B = R_B/R_N^0$ with $R_N^0 \equiv R_N(L = \xi_{T_c}) = R_N \xi_{T_c}/L_F$, where $\xi_{T_c} = \sqrt{\hbar D/2\pi T_c}$ (T_c is the superconducting transition temperature). In the calculation, we have assumed the retarded causality in the Green function. By using Eq. (13), we obtain two boundary conditions

$$2\Gamma_B \partial_x \,\hat{\gamma} =2 g_s \,\hat{\gamma} + f_s (\hat{\gamma}\,\hat{\sigma}_2\,\hat{\gamma} - \hat{\sigma}_2), \tag{22}$$

$$2\Gamma_B \partial_x \,\underset{\sim}{\hat{\gamma}} =2 g_s \,\underset{\sim}{\hat{\gamma}} + f_s (\underset{\sim}{\hat{\gamma}}\,\hat{\sigma}_2\,\underset{\sim}{\hat{\gamma}} - \hat{\sigma}_2). \tag{23}$$

Since $g_s(-E) = g_s^*(E)$ and $f_s(-E) = f_s^*(E)$, $-\hat{\gamma}^*(x, -E)$ and $\underset{\sim}{\hat{\gamma}}(x, E)$ satisfy the same boundary condition.

By numerically solving nonlinear differential equations (15) and (16) together with the boundary conditions (22) and (23), we will calculate local density of state (LDOS)

$$\frac{N(E)}{N_0} = \frac{1}{2}\mathrm{Tr}\left[\mathrm{Re}\hat{g}(E)\right], \tag{24}$$

and the pair function matrix

$$\begin{aligned} \hat{f}(E) &= \left[f_0(E)\hat{1} + \vec{f}\cdot\hat{\boldsymbol{\sigma}} \right] \vec{\sigma}_2 \\ &= \left[\begin{array}{cc} i f_1(E) + f_2(E) & -i f_3(E) - i f_0(E) \\ -i f_3(E) + i f_0(E) & -i f_1(E) + f_2(E) \end{array} \right], \end{aligned} \tag{25}$$

where N_0 is the normal DOS and $\vec{f} = (f_1, f_2, f_3)$. Here the components f_0, f_1, f_2, and f_3 correspond, respectively, to spin singlet $[(|\uparrow\downarrow\rangle - |\downarrow\uparrow\rangle)/\sqrt{2}]$, equal-spin triplets $[|\uparrow\uparrow\rangle - |\downarrow\downarrow\rangle/\sqrt{2}]$, $[|\uparrow\uparrow\rangle + |\downarrow\downarrow\rangle/\sqrt{2})]$, and hetero-spin triplet paring $[(|\uparrow\downarrow\rangle + |\downarrow\uparrow\rangle)/\sqrt{2}]$.

Since the diffusive limit is considered, the singlet component f_0 has an even-frequency symmetry while the triplet components f_i $(i = 1, 2, 3)$ have an odd-frequency symmetry. It should be noted that the y component of the magnetic moment $\boldsymbol{V}(x)$ is zero in this paper [see Eq. (7)]. As a consequence the equal-spin triplet component f_2 is always zero.

III. RESULTS

In this section we study the LDOS and the zero-energy peak (ZEP) in LDOS for the cases of the uniform and nonuniform magnetization in a systematic manner. In order to show the robustness of the ZEP induced by spin-triplet odd-frequency paring, we calculate phase diagrams of the ZEP and the pair amplitudes as functions of several variables. We also show how to detect signatures of the long-range triplet-paring experimentally.

A. Local density of states and pair functions

Let us first discuss the LDOS for the uniform magnetization case, *i.e.*, $\alpha = 0$. In the calculation, we set $E_{\mathrm{ex}}/2\pi T_c = 0.1$ and $R_N^0/R_B = 0.2$ (a moderate proximity-effect regime). We show the F layer thickness L_F dependence of the LDOS $N(E)$ at the edge of F2 layer, namely at $x = L_F$ in Figs. 2(a)∼(c). When L_F/ξ_{T_c} is very small or the Thouless energy E_{Th} is much larger than E_{ex}, *i.e.*, $E_{\mathrm{Th}} = \hbar D/L_F^2 \gg E_{\mathrm{ex}}$, the mini gap is formed due to the proximity effect. In this case we can neglect magnetic effects and then the magnitude of the mini gap is approximately given by[8]

$$E_{\mathrm{g}} = \frac{E_{\mathrm{Th}}}{1 + \frac{R_B}{R_N}}, \tag{26}$$

as in the case of diffusive S/N(normal metal) junctions. By increasing L_F, $E_{\mathrm{Th}}(\sim L_F^{-2})$ is decreased. Eventually, if a resonant condition $E_{\mathrm{ex}} = E_{\mathrm{mg}}$ is satisfied, the

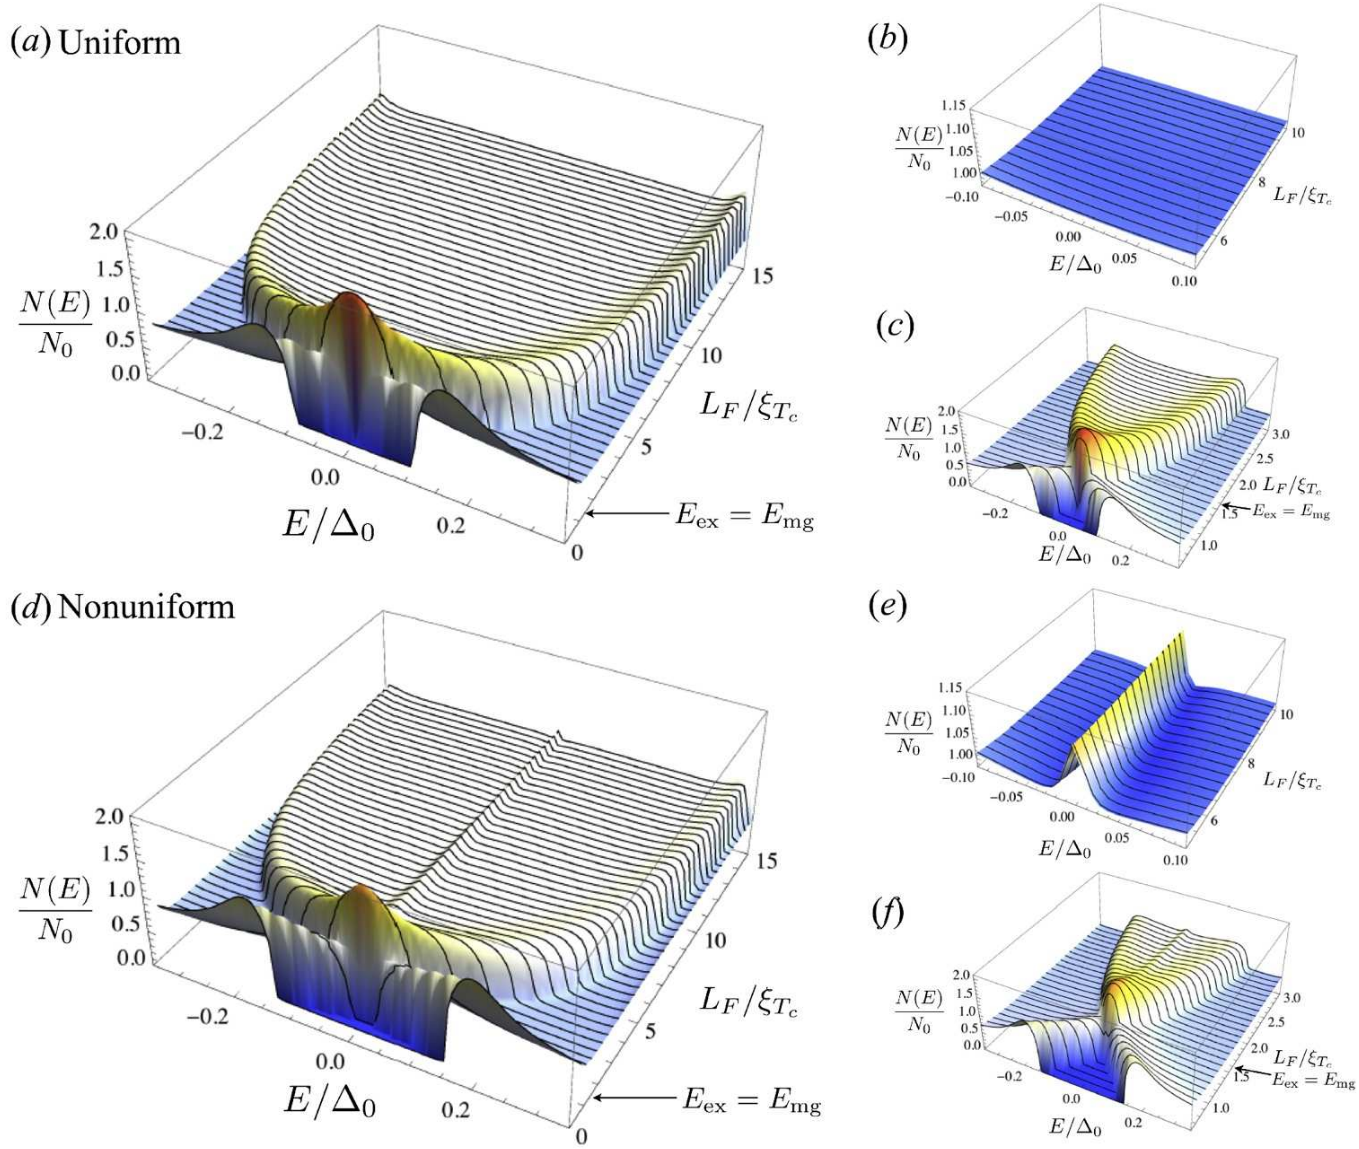

FIG. 2: (Color online) The local density of states (LDOS) $N(E)$ at the edge of the F_2 layer *i.e.*, $x = L_F$, as a function of energy E and the F layer thickness L_F for an SF junction with (a) an uniform ($\alpha = 0$) and (d) a nonuniform ($\alpha = \pi/2$) magnetization with $L_{F1} = 0.5\xi_{T_c}$, $E_{\rm ex}/2\pi T_c = 0.1$, and $R_N^0/R_B = 0.2$. N_0, Δ_0, and ξ_{T_c} are the normal state LDOS, the superconducting gap, and the coherence length at $T = T_c$, respectively. Panels (b) and (e) are magnified figures of (a) and (d) near $E = 0$, respectively. Panels (c) and (f) are magnified figures of (a) and (d) around the small L_F regime, respectively. The arrows indicate the resonant condition $E_{\rm ex} = E_{\rm mg}$, where $E_{\rm mg}$ is the mini gap in the case of $E_{\rm ex} = 0$.

mini gap is closed completely [see Figs. 2(a) and (c)].[69] As a consequence, the zero-energy peak (ZEP) is developed. However, if we increase L_F or decrease $E_{\rm Th}$ further, the LDOS profile near $E = 0$ becomes almost flat because the mini-gap edges move outwards toward the superconducting-gap edge. Therefore, the ZEP can be realized only near the resonant condition $E_{\rm ex} = E_{\rm mg}$.[70,71]

In order to see more clearly this point, we have plotted the zero-energy density of state $N(0)$ and the amplitude of the pair functions $|f_i(0)|$ ($i = 0, 1, 3$) as a function of L_F in Fig. 3(a). In the uniform-magnetization case, long-range triplet components f_1 and f_2 are completely absent.[10] Moreover near the resonant condition $E_{\rm ex} = E_{\rm mg}$, although the fraction of the short-range triplet component $f_3(0)$ is larger than the singlet one $f_0(0)$, both components coexist with each other. These observations are consistent with previous result.[18,29]

On the other hand, in the case of a nonuniform magnetization ($\alpha = \pi/2$), the behavior of $N(0)$ is drastically different from the uniform case due to the appearance of long-range spin-triplet paring. The LDOS at the edge of F_2 layer as a function of L_F is shown in Figs. 2(d)∼(f).

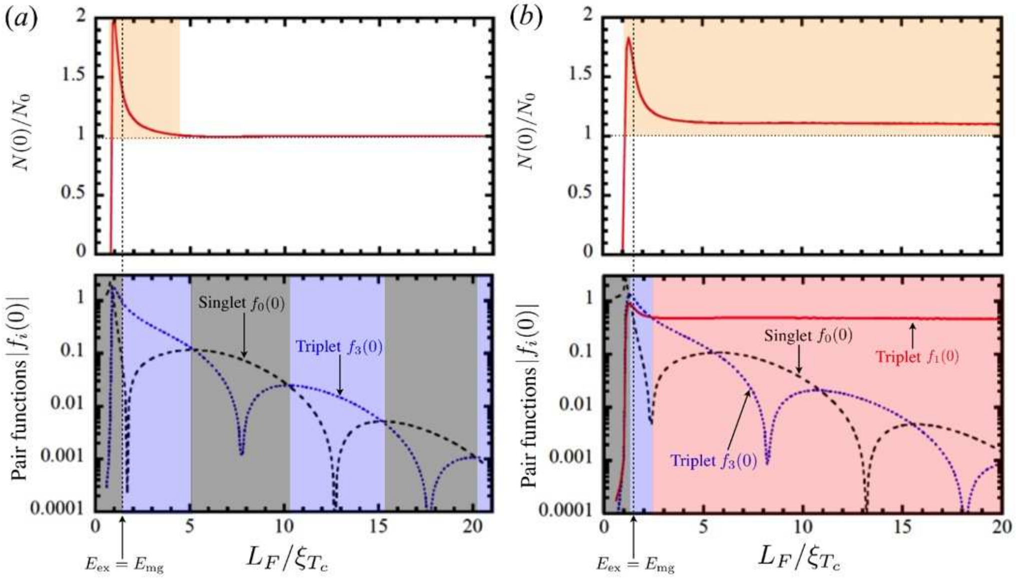

FIG. 3: (Color online) (a) The zero-energy LDOS $N(0)$ and the absolute value of the zero-energy pair-functions $f_i(0)$ as a function of the F layer thickness L_F at the edge of the F2 layer ($x = L_F$). f_0 (black dashed line), f_3 (blue dotted line), and f_1 (red solid line) are the shot-range singlet, the short-range triplet, and the long-range triplet component, respectively. The vertical dotted-line is corresponding to the resonant condition $E_{\rm ex} = E_{\rm g}$. The parameters are $L_{F1} = 0.5\xi_{T_c}$, $E_{\rm ex}/2\pi T_c = 0.1$, and $R_N^0/R_B = 0.2$.

As clearly seen from Figs. 2(d) and (e), not only near the resonant condition but also a wide range of L_F, the ZEP is developed.

In order to understand the physical origin of the ZEP, we have plotted the zero-energy LDOS $N(0)$ and the pair functions $f_i(0)$ at the edge of F_2 layer ($x = L_F$) as a function of L_F in Fig. 3(b). If the long-range triplet component $f_1(0)$ is largely developed in comparison with short-range components (f_0 and f_3), the ZEP is highly enhanced. Although short range components show an exponentially-damped oscillation as a function of L_F, the long-range one decays considerably slowly with increasing L_F. This is due to the fact that long-range pairs ($|\uparrow\uparrow\rangle, |\downarrow\downarrow\rangle$) have zero center-of-mass momentum as in the case of singlet-pairs in conventional SN junctions. Therefore in the case of the long F_2 layer *i. e.*, $L_{F2}/\xi_{T_c} \gg 1$, one can have almost pure long-range triplet component near the edge of F_2 layer.

It is important to note that the dependences of $N(0)$ and $f_1(0)$ on L_F in the regime $L_F/\xi_{T_c} \gg 1$ are closely related to each other as demonstrated in Fig. 3(b). This can be explained as follows. If the long-range component $f_1(0)$ is fully developed, the zero-energy LDOS is approximately given as

$$\frac{N(0)}{N_0} = \frac{1}{2}\mathrm{Tr}\left[\mathrm{Re}\hat{g}(0)\right] \approx \sqrt{1-|f_1(0)|^2}, \qquad (27)$$

as can be obtained by using the normalization condition

$$\hat{g}^2 + \hat{f}\underset{\sim}{\hat{f}} = \hat{1}. \qquad (28)$$

Thus the L_F dependence of ZEP is closely related to that of the long-range triplet component $f_1(0)$.[10] Therefore we can conclude that a systematic ZEP measurement by changing L_F gives a strong evidence for the signature of the long-range spin-triplet correlations. In Sec. IV. C we will discuss in more detail the ways to discriminate experimentally between the short- and long-range triplet components.

B. Robustness of the zero-energy peak

Heretofore only limiting cases, e.g., a very weak exchange field,[44] a very strong exchange field (like half metals),[19,20] and a very thin F layer thickness ($L_F \ll \xi_{\mathrm{T_c}}$),[19] have been explored in previous theoretical studies on the ZEP in SF junctions. Moreover in order to validate the linearization approximation for the Usadel equation, only the weak proximity-effect regime (equivalently $R_N/R_B \ll 1$) has been explicitly investigated. Therefore the natural question to ask is *how robust the presence of the ZEP induced by spin-triplet odd-frequency paring is in reality?* To solve this crucial issue, we will calculate the zero-energy LDOS $N(0)$ and the pair amplitudes $f_i(0)$ by systematically varying several parameters, *i. e.*, (1) the exchange energy $E_{\rm ex}$ and (2) the barrier resistance R_B which is a control parameter for the proximity effect *without* the linearized approximation . Then we would like to show the robustness for the presence of ZEP induced by spin-triplet odd-frequency paring.

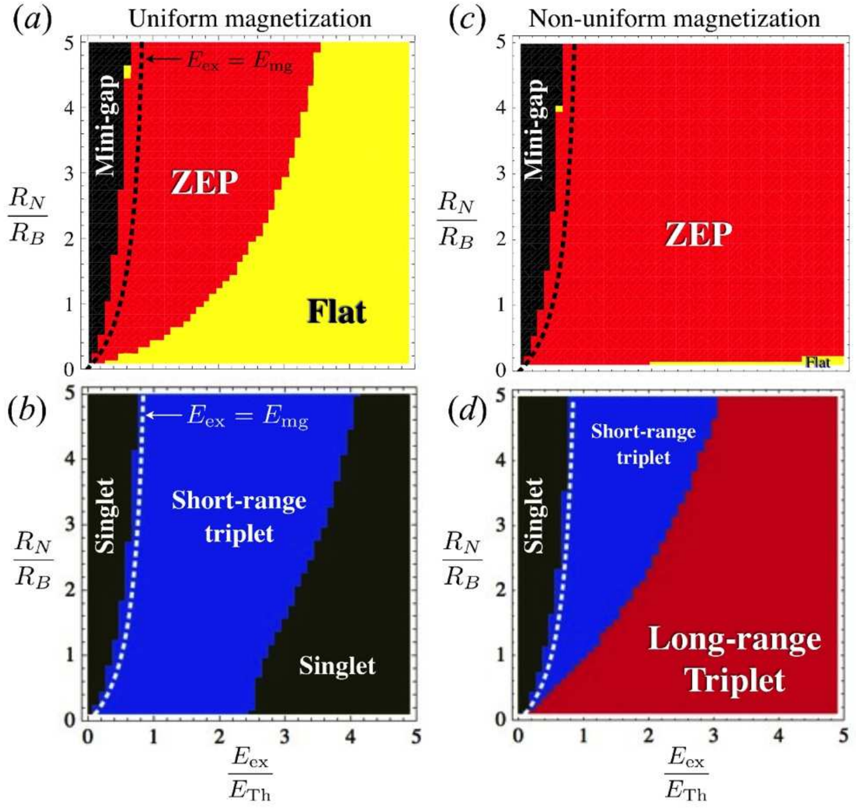

FIG. 4: (Color online) The phase diagram of the zero-energy LDOS $N(0)$ at $x = L_F$ as a function of R_N/R_B and $E_{\rm ex}/E_{\rm Th}$ for an SF junction with (a) an uniform ($\alpha = 0$) and (b) a nonuniform magnetization ($\alpha = \pi/2$), where $L_{F1} = 0.5\xi_{T_c}$ and $L_F = 4.0\xi_{T_c}$. The mini gap, the zero-energy-peak (ZEP), and the flat phase are respectively defined by the region with $N(0)/N_0 < 0.98$, $N(0)/N_0 > 1.02$, and $1.02 \le N(0)/N_0 \le 0.98$. Panels (c) and (d) show the phase diagram of a most dominant component of pair amplitudes at $x = L_F$ for an SF junction with an uniform and a nonuniform magnetization, respectively. Black, blue, and red regions are the singlet f_0, the short-range triplet f_3, and the long-range triplet f_3-dominant phase, respectively. The dotted lines are corresponding to the resonant condition $E_{\rm ex} = E_{\rm mg}$.

In Fig. 4 we show the phase diagram of $N(0)/N_0$ and a most dominant component of pair amplitudes for an SF junction with the uniform [Figs. 4(a) and (b)] and the nonuniform magnetization-configuration [Figs. 4(c) and (d)] as a function of R_N/R_B and $E_{\rm ex}/E_{\rm Th}$. In the calculation, we have assumed that $L_{F1} = 0.5\xi_{T_c}$ and $L_F = 4.0\xi_{T_c}$.

In the zero-energy LDOS phase diagram, following three phases have been realized, *i.e.*, (i) the mini-gap phase with $N(0)/N_0 \approx 0$, (ii) the ZEP phase with $N(0)/N_0 > 1$, and (iii) the flat phase with $N(0)/N_0 \approx 1$. In the calculation we have defined the ZEP phase as regions with $N(0)/N_0 > 1.02$ and the flat phase with $0.98 \le N(0)/N_0 \le 1.02$ as a matter of practical convenience. As was already discussed in Sec. III. A, in the case of the uniform magnetization, only the short-range components f_0 and f_3 exist. As a consequence, only in the vicinity of the resonant condition the ZEP phase is developed [see the dotted line in Figs. 4(a) and (b)].

In contrast, if we consider a nonuniform magnetization ($\alpha = \pi/2$), the ZEP phase is appeared in a wide range of the parameter region for $E_{\rm ex}/E_{\rm Th}$ and R_N/R_B as clearly shown in Fig. 4(c). This can be attributed to the appearance of the long-range triplet component $f_1(0)$ [see Fig. 4(d)]. From above results, one can conclude that in the SF junction with nonuniform magnetizations, *the existence of the ZEP induced by spin-triplet paring is very robust irrespective of the device and material parameters* as long as $E_{\rm ex}/E_{\rm mg} > 1$. Therefore the experimental observation of the ZEP gives a unequivocal evidence of the spin-triplet paring. This is one of the important findings in our work.

C. Zero-energy peak spectroscopy

In this section we will investigate the ZEP structure in more detail and propose an experimental method to explicitly detect a signature of long-range triplet paring through the ZEP measurement, so to say *the ZEP spectroscopy*. Moreover the possibility for observing *the singlet to triplet crossover* via the ZEP spectroscopy is discussed as well.

We have calculated the deviation of the zero energy LDOS $N(0)$ from the normal value N_0, *i. e.*, $|\delta\nu_0| \equiv |N(0)/N_0 - 1|$ at $x = L_F$ by changing L_F. In the calculation we have used $L_{F1} = 0.5\xi_{T_c}$ and $E_{\mathrm{ex}}/2\pi T_c = 0.1$ as in Fig. 3. In Fig. 5 we show a log plot of $|\delta\nu_0|$ as a function of L_F in the case of a moderate proximity regime ($R_N^0/R_B = 0.2$) and a strong proximity regime ($R_N^0/R_B = 1.0$). It should be noted that in the strong proximity regime, the well-used linearized Usadel approach is not justified at all.

In the case of an uniform magnetization ($\alpha = 0$), $|\delta\nu_0|$ shows the oscillatory damped behavior. This means that $\delta\nu_0$ changes its sign almost periodically with increasing L_F. Such a behavior is consistent with previous theoretical predictions[72–74] and also with experimental results.[75,76]

In contrast, the behavior of $|\delta\nu_0|$ for the case of inhomogeneous magnetization ($\alpha = \pi/2$) is drastically different from that for the uniform one. Due to the development of the long-range triplet component $f_1(0)$, $|\delta\nu_0|$ decay very slowly as a function of L_F. And apparently the sign of $\delta\nu_0$ is always *positive* as long as $E_{\mathrm{ex}} > E_{\mathrm{mg}}$ [see also Fig. 3(b)]. In this case, the typical decay length is given by $\xi_\delta = \mathrm{Re}\left[\sqrt{\hbar D/i\delta}\right]$, where δ is the imaginary part of the energy which accounts for inelastic process, for instance, the thermal excitation or the spin-orbit interaction. Throughout this paper we set $\delta/\Delta_0 = 10^{-4}$. From above results, we can conclude that by systematically measuring the zero energy LDOS as a function of L_F, we can explicitly distinguish between long-range (f_1) and short-range parings (f_0 and f_3).

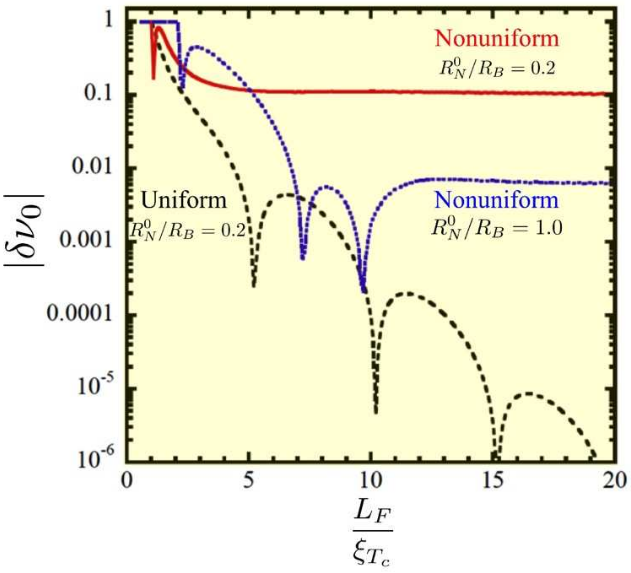

FIG. 5: (Color online) The zero-energy peak spectroscopy. The deviation of the zero energy LDOS $N(0)$ from the normal value N_0, *i. e.,* $\delta\nu_0 = N(0)/N_0 - 1$ at as a function of the F layer thickness L_F for an SF junction with $\alpha = 0$ (the black dashed line) and $\alpha = \pi/2$ (the red solid and blue dotted line) for different values of R_N^0/R_B. The LDOS is evaluated at $x = L_F$. Parameters are $L_{F1} = 0.5\xi_{T_c}$ and $E_{\mathrm{ex}}/2\pi T_c = 0.1$.

More interestingly, we have found a following peculiar feature in the strong proximity regime ($R_N^0/R_B = 1.0$). As clearly seen from the blue dotted curve in Fig. 5, a *crossover* from the short-range ($0 \leq L_F/\xi_{T_c} \lesssim 11$) to the long-range behavior ($L_F/\xi_{T_c} \gtrsim 11$) appears. In order to see more explicitly this crossover, we have also calculated pair functions as a function of L_F in Fig. 6 and found that dip positions of $|\delta\nu_0|$ are almost identical with crossover points between singlet- and triplet-dominant phases. It is important to note that such a singlet-to-triplet paring crossover can be regarded as an even-to-odd frequency paring one.

A physical origin of above remarkable phenomena can be explained as follows. If all the components $f_i(i =$

Spin	Singlet	Triplet	Singlet	Triplet
Frequency	Even	Odd	Even	Odd
Range		Short		Long
Sign of $\delta\nu_0$	—	+	—	+

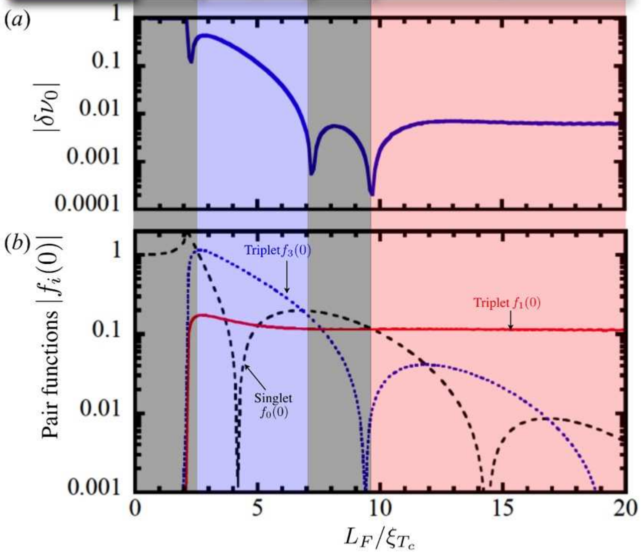

FIG. 6: (Color online) (a) The deviation of the zero-energy LDOS $N(0)$ from the normal value N_0, *i. e.*, $|\delta\nu_0| = |N(0)/N_0 - 1|$ at $x = L_F$ as a function of the F layer thickness L_F for an SF junction with a non-uniform magnetization ($\alpha = \pi/2$) in a strong proximity regime ($R_N^0/R_B = 1.0$). Panel (b) shows the absolute value of pair functions $f_i(0)$ at $x = L_F$ as a function of L_F. f_0 (black dashed line), f_3 (blue dotted line), and f_1 (red solid line) are the shot-range singlet, the short-range triplet, and the long-range triplet component, respectively. Parameters are $L_{F1} = 0.5\xi_{T_c}$ and $E_{\mathrm{ex}}/2\pi T_c = 0.1$. The gay, blue and red region are corresponding to singlet-, short-range triplet-, and long-range triplet-dominant phases. The upper table shows paring symmetries for a most dominant component and the sign of $\delta\nu_0$.

$0, \cdots, 3)$ coexist with each other, $\delta\nu_0$ can be expressed from (28) as[10]

$$\delta\nu_0 = \frac{N(0)}{N_0} - 1 \approx -\left|f_0(0)\right|^2 + \sum_{i=1,2,3} \left|f_i(0)\right|^2 , \qquad (29)$$

by assuming $|f_i| \ll 1$, and using the facts that $\mathrm{Im} f_0(0) = 0$ for the singlet component and $\mathrm{Re} f_i(0) = 0$ for triplet components $(i = 1, 2, 3)$.[10,37] Therefore, singlet and triplet components respectively give a negative and positive contribution to $\delta\nu_0$. So if the dominant component is changed from singlet to triplet (or from triplet to singlet) by increasing L_F, $\delta\nu_0$ changes its sign. This gives rise to a dip structure in the $|\delta\nu_0|$ vs L_F curve as shown in Fig. 6.

It is important to note that even in the weak or moderate proximity regime ($R_N^0/R_B < 1$) such a singlet-triplet crossover phenomena can be realized. As was demonstrated in Fig. 3(b), the long-range component $f_1(0)$ is largely enhanced in compared with strong proximity cases [Fig. 6(b)]. Therefore single crossover (from a short-range singlet to short-range triplet) is realized only at around the resonant condition. Similarly we can regard well known zero-energy LDOS oscillation as a function L_F in an *uniform* SF junction as a multiple (short-range) singlet to (short-range) triplet crossover [see Figs. 3(a) and 5].

Therefore we can explicitly conclude that *we can identify crossover points of the paring symmetry from dip positions of* $|\delta\nu_0|$. This remarkable feature has never been recognized in previous studies and is one of most important findings in our paper. From above results it is clear that the systematic LDOS measurement by changing the exchange field E_{ex}, the F layer thickness L_F, and the barrier resistance R_B gives a clear and unambiguous evidence of the novel long-range triplet odd-frequency paring.

Finally we would like to propose a systematic method to detect the signature of odd-frequency paring and observe the singlet-to-triplet crossover experimentally. Fig. 7(a) shows a scheme of an SF junction in contact with an STM tip to measure the differential conductance or the LDOS in the F layer. The spatial dependence of the LDOS of F in the strong proximity regime is plotted in Fig. 7(b). As clearly seen from Fig. 7(b), the measurement of the position dependence of the zero-energy LDOS would enable clear identification of long-range odd-frequency paring as well as the the singlet-to-triplet crossover. It should be noted that the spatial dependence of the LDOS of an inhomogeneous SF junctions for a *weak* proximity and small exchange field case has been investigated by Cottet.[44]

IV. SUMMARY

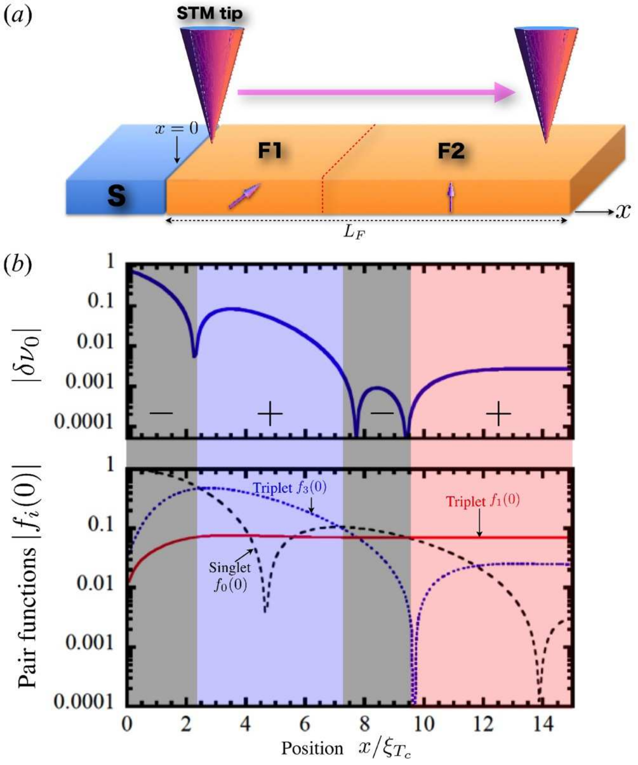

FIG. 7: (Color online) (a) Scheme of an inhomogeneous SF junction in contact with an STM tip. Panel (b) shows the position x dependence of $\delta\nu_0(0)$ and pair functions $f_i(0)$ $(i = 0, 1, 3)$ in the F layer, where ± is corresponding to the sign of $\delta\nu_0$. f_0 (black dashed line), f_3 (blue dotted line), and f_1 (red solid line) are the shot-range singlet, the short-range triplet, and the long-range triplet component, respectively. Parameters are $\alpha = \pi/2$, $L_{F1} = 0.5\xi_{T_c}$, $L_{F2} = 14.5\xi_{T_c}$, $R_N^0/R_B = 2.0$, and $E_{\mathrm{ex}}/2\pi T_c = 0.1$.

To conclude we have systematically investigated the superconducting proximity effect in SF junctions with an uniform and a nonuniform magnetization in terms of spin-triplet odd-frequency paring. By solving the nonlinear Usadel equation fully numerically, we have calculated the LDOS in a ferromagnet and found following remarkable results.

(1)In contrast to the case of the uniform magnetization,[70,71] the LDOS in SF junctions with a nonuniform magnetization has a zero energy peak in a wide range of parameters, indicating *the robust presence of the ZEP induced by the spin-triplet odd-frequency paring.*

(2)The ZEP height is damped very slowly with increasing L_F due to the development of long-range spin-triplet paring. This behavior is very contrast to uniform magnetization cases in which the zero energy LDOS shows exponentially damped-oscillation as a function of L_F.[72–76]

(3)The dip position of $|\delta\nu_0|$ is corresponding to the crossover-point between singlet and triplet or even and odd paring. This means that the ZEP spectroscopy gives us clear information on the paring-symmetry of Cooper pairs.

Above remarkable results clearly indicate that the experimental observation of the ZEP for SF junctions with a non-uniform magnetization provides a smoking gun for the existence of the novel spin-triplet odd-frequency paring.

In this paper, we have discussed proximity effect assuming spin-singlet s-wave superconductor as a bulk state of S. An extension to unconventional superconductors is possible based on more general boundary condition [77,78] taking account of the Andreev bound state. Proximity effect in spin-triplet p-wave superconductors is interesting[79–83] since odd-frequency pairing is also induced from bulk superconductor without the exchange energy.[84] In addition, we have especially focused on the LDOS. It is interesting to discuss the anomalous Meissner effect[85,86] and the surface impedance[87] due to the proximity effect by odd-frequency pairing.
